Evidence-Based Series 5-2

A Quality Initiative of the Program in Evidence-Based Care (PEBC), Cancer Care Ontario (CCO)

The Role of Endolaryngeal Surgery (With or Without Laser) versus Radiotherapy in the Management of Early (T1) Glottic Cancer

J. Yoo, C. Lacchetti, A. Hammond, R. Gilbert, and the Head and Neck Cancer Disease Site Group

Report Date: March 14, 2012

An assessment conducted in December 2016 deferred the review of Evidence-based Series (EBS) 5-2, which means that the document remains current until it is assessed again next year. The PEBC has a formal and standardized process to ensure the currency of each document (PEBC Assessment & Review Protocol).

The full Evidence-based Series 5-2 is comprised of 3 sections and is available on the CCO Website on the PEBC Head & Neck DSG page.

Section 1: Guideline Recommendations
Section 2: Evidentiary Base
Section 3: EBS Development Methods and External Review Process

For information about the PEBC and the most current version of all reports, please visit the CCO website at http://www.cancercare.on.ca/ or contact the PEBC office at:

The Role of Endolaryngeal Surgery (With or Without Laser) versus Radiotherapy in the Management of Early (T1) Glottic Cancer: Guideline Recommendations

J. Yoo, C. Lacchetti, A. Hammond, R. Gilbert, and the Head and Neck Cancer Disease Site Group

A Quality Initiative of the Program in Evidence-Based Care (PEBC), Cancer Care Ontario (CCO)

Report Date: March 14, 2012

QUESTION
In patients with early (T1) glottic cancer, what is the role of endolaryngeal surgery (with or without laser) versus radiation therapy, in terms of survival, locoregional control, laryngeal preservation rates and voice outcomes?

TARGET POPULATION
The target population of this guideline is adult patients with previously untreated early (T1) glottic cancers.

INTENDED USERS
This guideline is intended for use by clinicians and healthcare providers involved in the management or referral of adult patients with early (T1) glottic cancer.

RECOMMENDATION
For patients with early (T1) glottic cancer, recommended treatment options include the equally effective endolaryngeal surgery, with or without laser, or radiation therapy. The choice between treatment modalities should be based on patient and clinician preferences and general medical condition.

QUALIFYING STATEMENT
There is currently no well-designed, prospective, randomized controlled trial (RCT) that compares endolaryngeal surgery and radiation therapy. Thus, these recommendations are based primarily on other comparative study designs. Although not substantiated by the evidence, several factors are important considerations when deciding between surgery and radiotherapy for early glottic cancer. Location of disease is one factor. Anterior commissure
involvement may be a factor that favours a recommendation of radiotherapy over surgery due to a common opinion that voice outcomes are particularly affected. Tumours localized to the midportion of the vocal fold, and where endoscopic accessibility is uncompromised, may be considered ideal candidates for surgery. Other important practical considerations include the ability for patients to tolerate a general anaesthetic, which is required for surgery. In contrast, radiotherapy requires patient cooperation for daily treatment for four to six weeks. Partial laryngeal surgery, including revision endoscopic surgery, is possible for local recurrence following surgery. However, re-irradiation is not an option in cases of recurrence.

KEY EVIDENCE

There is a lack of high-quality evidence to explicitly inform the guideline question. Notwithstanding, the recommendation is based on the best available evidence and a consensus of expert clinical opinion of the Head and Neck Cancer Disease Site Group (DSG).

One meta-analysis, fifteen cohort studies and two cross-sectional studies comparing endolaryngeal surgery (with or without laser) to radiation therapy in patients with early glottic cancer comprised the evidence base.

- No statistically significant differences in overall survival or disease-free survival were detected. One retrospective cohort study (1) did report a significant (p=0.003) 15-year cause-specific survival benefit in surgically treated patients (100%) over those treated with radiation therapy (91%). This result was not consistent with four other retrospective cohort studies (2,3-5) that also considered cause-specific mortality and showed no significant differences. The meta-analysis [6] detected no statistically significant laryngectomy-free survival benefits associated with laser surgery when compared to radiation therapy (odds ratio [OR], 0.73; 95% confidence interval [CI], 0.39-1.35).

- One meta-analysis (6) found no statistically significant difference in local control between radiation therapy and laser surgery (OR, 0.66; 95% CI, 0.41 to 1.05). One (7) of eight retrospective cohort studies reported a marginally significant better control rate in surgically treated patients (89%) over those treated with radiotherapy (75%) when only T1a patients were considered (p=0.05). One retrospective cohort study [1] also reported a significant difference in recurrence rates favouring surgery. Thurnher et al (1) found a recurrence rate of 30.5% in those undergoing radiation therapy versus 9.9% in the patients treated with laser excision (p=0.001). The remaining five studies did not report any such significant differences in recurrence rates between treatment groups.

- Laryngeal preservation rates were found to be better with surgery, (with or without laser) as compared to radiation in five studies (1,5,7-9), while one study found a marginally significant better preservation rate with radiation therapy (p=0.051) (10).

- Post-treatment voice and speech quality was assessed by clinician perceptual analysis in one retrospective cohort study (11), which found that the difference between radiation therapy patients and those treated surgically did not reach statistical significance. In five studies that analyzed patient self-perception, three (12-14) found no statistically significant difference between treatment groups, one (15) found radiation therapy patients scored significantly better, and one (16) study reported surgically treated patients scored better. One meta-analysis (6) found conflicting results. It detected significantly better maximum phonation time and fundamental frequency in the radiation therapy patients but reported that the perturbation measures of jitter and shimmer significantly favoured the patients undergoing transoral laser surgery.
FUTURE RESEARCH

Carcinoma of the glottis is usually diagnosed in the early phase, and both modalities of treatment have shown high cure rates. However, controversies in the treatment of early glottic cancer remain because of the lack of high-quality prospective analyses comparing endoscopic surgery versus radiotherapy. There is no evidence in favour of one treatment modality when considering the likelihood of local control or overall survival. There is a suggestion that radiotherapy may be associated with less measureable perturbation of voice as compared to surgery but no significant differences were seen in patient perception. The likelihood of laryngeal preservation may be higher when surgery can be offered as initial treatment. Future research should focus on conducting RCTs or prospective comparative studies, with ample follow-up time, that focus on functional outcomes of patients with early glottic cancer.

The Role of Endolaryngeal Surgery (With or Without Laser) versus Radiotherapy in the Management of Early (T1) Glottic Cancer: Evidentiary Base

J. Yoo, C. Lacchetti, A. Hammond, R. Gilbert, and the Head and Neck Cancer Disease Site Group

A Quality Initiative of the Program in Evidence-Based Care (PEBC), Cancer Care Ontario (CCO)

Report Date: March 14, 2012

QUESTION
In patients with early (T1) glottic cancer, what is the role of endolaryngeal surgery (with or without laser) versus radiation therapy, in terms of survival, locoregional control, laryngeal preservation rates and voice outcomes?

INTRODUCTION
Cancer of the glottis, the region of the larynx that contains the true vocal cords, is the most common noncutaneous malignancy of the head and neck [1]. An estimated 1,150 new cases of laryngeal cancer will be diagnosed in Canada in 2011, with men being four times more likely to develop the disease than women [2]. While the incidence rates of larynx cancer are significantly decreasing for both men and women, an estimated 490 Canadians are still expected to succumb to the disease this year [2]. The decreasing incidence and mortality rates reflect a decrease in the use of proven risk factors for the disease, specifically tobacco and alcohol use.

Treatment options for early glottic cancer include transoral microsurgery (with or without laser), radiotherapy or, infrequently, open surgery. Regardless of the treatment modality, the goal remains to cure, while avoiding total laryngectomy [3]. Additional goals include maintaining voice quality, minimizing the risk of serious complications and minimizing costs [4].

There is continuing debate about whether radiation therapy or surgery, with or without laser, is the superior treatment for early glottic cancer. The evidence to date has been insufficient to resolve the controversies, particularly because of the paucity of prospective randomized trials. Furthermore, opinions about optimal therapy have been demonstrated to vary across disciplines [1] and between countries [5]. The purpose of this systematic review and evidence-based guideline is to systematically review reported studies
in the literature, compare outcomes among these studies, and provide guidance on the effectiveness of the two most common treatment options for early glottic cancer: endolaryngeal surgery and radiotherapy.

METHODS

The evidence-based series (EBS) guidelines developed by the PEBC, (CCO), use the methods of the Practice Guidelines Development Cycle [6]. For this project, the core methodology used to develop the evidentiary base was the systematic review. Evidence was selected and reviewed by two members of the PEBC Head and Neck Cancer Disease Site Group (DSG) (see Appendix 1 for a complete list of DSG members) and one methodologist.

The body of evidence in this review is comprised primarily of retrospective comparative and cross-sectional studies. That evidence forms the basis of the recommendations in Section 1 developed by the Head and Neck Cancer DSG. The systematic review and companion recommendations are intended to promote evidence-based practice in Ontario, Canada. The PEBC is supported by the Ontario Ministry of Health and Long-Term Care, and all work produced by the PEBC is editorially independent from its funding source.

Literature Search Strategy

The literature was searched using MEDLINE (OVID: 1996 through December Week 4, 2010), Ovid MEDLINE(R) In-Process & Other Non-Indexed Citations (January 10, 2011), EMBASE (OVID: 1996 through January 2011, Week 1), and the Cochrane Library (OVID: 4th Quarter 2010). In addition, the proceedings of the meetings of the American Society of Clinical Oncology (ASCO), the American Society of Therapeutic Radiology and Oncology (ASTRO), and the Canadian Association of Radiation Oncology (CARO) were all searched for relevant abstracts in the years 2007 to the most recently available, 2010. Reference lists of studies deemed eligible for inclusion in the systematic review were scanned for additional citations.

The literature search of the electronic databases combined disease-specific terms (squamous cell carcinoma, cancer, malignancy, neoplasm, tumour) along with site-specific terms (larynx, vocal cord, glottis, subglottic, supraglottic) and treatment-specific terms (irradiation, radiotherapy, surgery, endoscopic surgery, microsurgery) for all study designs (Appendix 2).

In addition to this search of the electronic databases, an Internet search of Canadian and international health organizations and the National Guidelines Clearinghouse was conducted for existing guidelines and systematic reviews relevant to our research question. Guidelines were included if they were published since 2006 in English. This environmental scan yielded three practice guidelines [3,7,8] and one consensus statement [9]. The Working Group of the Head and Neck Cancer DSG decided that proceeding with a new systematic review that includes the latest research was warranted, given the time elapsed or lack of reporting of the literature included in these practice guidelines.

Study Selection Criteria

Inclusion Criteria

Articles were eligible for inclusion in this systematic review of the evidence if they were the following:

- Abstracts or full reports of randomized trials or non-randomized comparative studies that evaluated endolaryngeal surgery, with or without laser, and radiation therapy in the primary treatment of early (T1) glottic cancer.
- Reports of systematic reviews or evidence-based guidelines with systematic reviews that addressed the guideline question.
- Retrospective or cross-sectional studies that included a minimum of 50 patients.
• Studies including patients with greater than T1 disease if the majority of patients had T1 disease and if the outcome of interest was other than post-treatment voice quality.
• Studies reporting at least one of the following outcomes: survival, local or locoregional control, larynx preservation rate, or post-treatment voice quality.

**Exclusion Criteria**
Articles published in languages other than English were excluded because of limited translation resources.

**Quality Appraisal**
Systematic reviews and meta-analyses were assessed for quality using the Assessment of Multiple Systematic Reviews (AMSTAR) tool [10]. The quality of primary studies included assessments for study design, type of data collection, balance between the treatment groups, differences in baseline patient characteristics, and reporting of such differences.

**Synthesizing the Evidence**
If clinically homogenous data from two or more studies are available, the data will be pooled using the Review Manager software [11]. Pooled adjusted hazard ratios (HRs) for survival would be obtained using a random effects model. The presence of statistical heterogeneity would be evaluated using the $\chi^2$ test for heterogeneity and the I$^2$ percentage. A probability level for the $\chi^2$ statistic less than or equal to 10% (p≤0.10) and/or an I$^2$ greater than 50% would be considered indicative of statistical heterogeneity.

**RESULTS**
**Literature Search Results**
A total of 1,045 studies were identified in the complete literature search, of which 146 were pulled for full-text review. The two systematic reviews, one with a meta-analysis, and 17 primary studies that met the inclusion criteria are included in this review. (See Appendix 3 for the flow diagram of search results). Abstracts are not used in PEBC guidelines.

**Study Design and Quality**
The one meta-analysis [12] was assessed for methodological quality using the AMSTAR tool [10] and received a moderate overall rating, with possible issues around the quality assessment of included studies. The publication did not include a literature search strategy nor report on a priori methods of assessment of included studies. Without such documentation, the methodological rigour could not be adequately assessed. The systematic review by Dey et al [13] was also assessed for quality using the AMSTAR tool [10] and did not suffer from any methodological shortcomings.

Fifteen cohort studies and two cross-sectional studies were included in this review (Table 1). Data collection occurred prospectively in three studies [14-16] and retrospectively in fourteen. Six studies [15-20] had a disproportionate number of patients in one treatment group, while 10 showed a balance between treatment groups. One study [21] did not report the number of patients included in the radiotherapy group and, as such, balance between treatment groups could not be determined. Sixteen of the included studies reported on baseline characteristics. Of these, nine [16,18,20,22-27] specifically tested for differences between treatment groups and reported having done so, and two found significant differences [22,27]. While the remaining seven studies failed to discuss any existing differences in baseline characteristics, balance between treatment groups appears to have been attained in five of these studies [14,15,17,19,28].
Synthesizing the Evidence

Pooling of the study results was deemed inappropriate due to both the lack of adequately designed studies and the heterogeneity that exists between the different study populations and modalities based on the year of administration. Instead, results of each study are presented individually in a descriptive fashion. Where statistical analyses were not reported in a study, the authors of this guideline executed their own analyses of the data, using the statistical software package STATA version 11 [29]. Proportions were compared using a $\chi^2$ test for values greater than 5 and the Fisher’s Exact Test for values less than or equal to 5. Values of $p<0.05$ were regarded as significant. The analyses conducted by the authors are distinguished from those reported in the papers by an asterisk (*), which appears next to the $p$-value in the tables.

Outcomes: Oncologic Outcomes

**Survival**

One recent systematic review by Dey et al. [13], an update of a Cochrane Review first published in 2002, included only randomized controlled trials (RCTs) that compared open surgery, endolaryngeal resection and/or radiotherapy. Only one RCT, published in 1990, that included an adequate number of patients with early glottic cancer was identified. Ogoltsova et al [32] found that five-year survival for T1 tumours was 100% in those undergoing surgery and 91.7% in the radiotherapy group. Disease-free survival at five-years in T1 tumours was 100% following surgery and 71.1% following radiotherapy. Neither of these differences was statistically significant. However, Dey et al [13] reported that the trial was compromised by both methodological and analytical deficiencies and, as such, deemed the evidence insufficient to guide management decisions. Concerns about the methodology of this trial included randomization that was possibly not concealed, the unbalanced number of patients in each group, inadequate staging prior to treatment, poor follow-up, and treatment regimens that were not standardized and likely suboptimal [13].

A recent meta-analysis by Higgins et al [12] compared oncologic outcomes of external radiation to transoral laser surgical excision in the treatment of early glottic cancer. When the laryngectomy-free survival data from four head to head comparison studies were pooled, a trend favouring CO2 laser over radiation therapy was revealed (OR, 0.73; 95% CI, 0.39 to 1.35). However, these results were not statistically significant.

Eleven primary studies reported survival outcomes in patients treated with radiotherapy versus those treated with surgery, with or without laser, for early glottic cancer (Table 2). No significant difference in overall or disease-free survival was detected between the different treatment modalities.

When considering cause-specific death from laryngeal cancer, Thurnher et al [19] found significantly higher mortality in the RT group than in those undergoing surgery (HR, 9.89; 95% CI, 2.16 to 45.39, p=0.0032). The authors attributed this difference to additional and earlier relapses in the RT patients compared to the surgical group. Mahler et al. [27], however, found no significant difference. Survival outcomes appear in Table 2.

*p-value cannot be calculated because the number of patients in the RT group was not available

**Locoregional Control**

One meta-analysis and ten additional primary studies not included in the meta-analysis reported local control or recurrence rate (Table 3).

In the meta-analysis of 6 direct head-to-head comparisons, Higgins et al [12] found no statistically significant difference in local control between radiation therapy and laser surgery (OR, 0.66; 95% CI, 0.41 to 1.05). Similarly, seven primary studies [18,21-23,26,27,31] found no significant difference in the local control rate between surgical or radiation therapy patients. However, Foote et al [17] reported a 100% local control rate in radiotherapy patients versus 88% in surgical patients (p=0.004). In considering only T1a patients, Sjogren et al [26] found a marginally significant difference at five years, where 89% of surgical patients experienced local control versus 75% of radiotherapy patients (p=0.05). Statistical
testing of the data from Scola et al [21] was not possible because the number of patients in the radiation therapy group was not reported.

Five studies [19,21-23,28] specifically considered local recurrence rates as an outcome of interest. A significant difference favouring surgery was calculated by the authors of this systematic review from the data of Thurnher et al [19] (p<0.0001). However, analyzing the data from Brandenburg [28], Bron et al [23] and Schrijvers et al [22] found no such difference between the surgical and radiation therapy treatment groups. Again, statistical testing of the data from Scola et al [21] was not possible because of lack of reporting. These results appear in Table 3.

**Larynx Preservation**

Ten studies considered laryngeal preservation rate as an outcome of interest, with five of these studies [19,22,26,30,31] showing a significant benefit favouring surgical patients. Laryngeal preservation rates appear in Table 4.

Mahler et al [27] found a significant difference in total laryngectomy rates between the surgery and radiation groups, with an odds ratio for laryngectomy in radiation therapy patients 13.5 times that of laser treated patients for the first three years after treatment (p=0.001).

Outcomes: Voice and Speech Quality

One meta-analysis and six primary studies not included in the meta-analysis reported post-treatment voice assessments in patients with T1 glottic cancer (Table 5). Six studies performed perceptual voice assessments, one of which used a clinician-rated tool and five of which used patient self-perception tools. The meta-analysis considered the assessment of acoustic and aerodynamic voice parameters.

Clinician Perceptual Analysis

In 18 patients with T1a glottic carcinoma, Rosier et al [25] conducted a perceptual voice rating by speech therapists, who blindly evaluated recorded voices and rated quality on a visual scale. An overall trend towards less hoarseness and breathiness after radiotherapy than after laser microsurgery was reported. However, this difference did not reach statistical significance (p>0.05).

Patient Self-perception Analysis

Dinapoli et al [24] reported RT patients scored significantly better on the Global Voice Handicap Index (VHI) than did surgical patients (p<0.0001). Patients treated with radiotherapy also had significantly better scores on the physical (p=0.0023), functional (p<0.0001) and environmental (p<0.0001) categories of the VHI. In contrast, Peeters et al [14] reported RT patients scored significantly worse on five of 30 VHI statements than did surgically treated patients. Furthermore, surgical patients also had a significantly better mean VHI score (p<0.05).

Utilizing two head and neck specific quality of life questionnaires, Smith et al [16] found no significant difference between treatment groups in patient-reported problems with swallowing, chewing, speech, taste, saliva, pain, activity, recreation, or appearance.

Investigating quality of life outcomes after treatment, Oridate et al [15] found no significant difference in Voice-Related Quality of Life (VRQOL) or VHI-10 scores in patients treated with radiotherapy or laser surgery. Similarly, Osborn et al [18] found no significant difference between laser surgery and radiotherapy-treated patients in either the total VRQOL.
However, a trend toward higher scores in the RT group for physical functioning was observed (p=0.05).

**Acoustic and Aerodynamic Analysis**

Higgins et al. [12] identified nine retrospective comparative studies that considered objective voice outcomes in patients undergoing RT or transoral laser surgery. Pooling of the weighted mean differences significantly favoured the RT patients with respect to Maximum Phonation Time (p<0.00001) and Fundamental Frequency (p<0.00001). Phonation Intensity Range also favoured the RT patients, but the difference was not statistically significant (p=0.54). The perturbation measures of jitter and shimmer, in contrast, significantly favoured the patients undergoing transoral laser surgery (p<0.00001 and p=0.002, respectively).

\(^1\)The VHI consists of an overall question on the quality of the voice and 30 statements on voice-related aspects in daily life. Summarizing the scores on the 30 statements leads to a total VHI score ranging from 0 to 120. A higher score corresponds to a worse voice-related functional status.

\(^2\)The V-RQOL is a 10-item questionnaire that provides scores in two component domains: social/emotional and physical functioning. A composite of these two scores provides an overall measure of voice-related quality of life. Total scores range from 0 to 100, with a higher score indicating better voice-related quality of life.

\(^3\)Breathiness is a determination of the turbulent noises in the voice, vocal height is a measure of the voice pitch and vocal instability represents a perturbation due to variability in the vibrating frequency.

**ONGOING TRIALS**

The US National Institutes of Health’s clinical trial registry (http://www.clinicaltrials.gov) was searched on July 14, 2011. Two relevant RCTs were identified and are described in Table 6. In addition, the 2010 Cochrane review by Dey et al [13] listed two further studies in their ongoing trials section that were not identified in our search. These too appear in Table 6.

**DISCUSSION**

Taking into account the results from two systematic reviews, one with meta-analysis, and 20 primary studies, it becomes apparent that the oncologic outcomes are similar between patients treated with radiotherapy or endolaryngeal surgery, with or without laser. Other factors, including voice quality following treatment and the likelihood of subsequent laryngectomy, thus may be currently more important in treatment decision making for early glottic cancer. The preponderance of the retrospective data would suggest that post-treatment quantitative acoustical and aerodynamic voice measurements may favour radiotherapy but patient perception of voice quality did not demonstrate significant differences between treatment modalities. Laryngeal preservation rates were seen to be higher in patients treated with primary surgery. The likelihood of requiring total laryngectomy at some point in patients initially treated with radiation was consistently higher in retrospective studies that assessed this outcome.

With each treatment modality in the management of early glottic cancer being fundamentally different, there is support for both therapies as primary treatment options [33]. Radiotherapy requires patient cooperation for daily treatment for four to six weeks and re-irradiation is not an option in cases of recurrence. Endolaryngeal surgery requires general anaesthesia which may be contraindicated in some patients [27]. Although not substantiated by the evidence, several other factors are important considerations when deciding between surgery and radiotherapy for early glottic cancer. The location of disease is one factor. Anterior commissure involvement may be a factor that favours a recommendation of radiotherapy over surgery due to a common opinion that voice outcomes are particularly affected. Tumours localized to the midportion of the vocal fold, and where endoscopic accessibility is uncompromised, may be considered ideal candidates for surgery. Such practice patterns may be an important confounding variable in comparison studies, since T1b tumours (anterior commissure involvement) have been shown to be associated with higher rates of local relapse as compared to T1a tumours. Although beyond the scope of this systematic review, cost-utility is an increasingly important factor also being considered.

Several limitations of this systematic review should be noted. Varying inclusion criteria between studies were observed. Some studies excluded patients with carcinoma in

</table>
situ while others included such patients. Cohen et al [34] found the extent of surgical resections differed among the studies included in their meta-analysis. The authors surmised that, in an attempt to avoid larger resection, more invasive tumours may have been preferentially treated with radiotherapy, thereby producing lower VHI scores in such treated patients [34]. Particularly in the case of post-treatment voice quality studies, the small sample size of included patients is also of concern.

In general, the Head and Neck DSG places greater weight on results from high quality studies, namely RCTs, when making clinical recommendations. In the absence of such high quality evidence, data from other study designs are considered. The systematic review on the topic of surgery versus radiation therapy in early glottic cancer revealed very little high quality evidence. The available literature on the treatment of early glottic cancer is comprised exclusively of non-randomized data, with the vast majority being retrospective in nature. Such study designs are inherently more susceptible to bias and difficult to compare and interpret. In light of the paucity of high-quality evidence on this topic, and the interest expressed by clinicians for guidance in this area, the Head and Neck DSG proceeded with the collection and inclusions of the best available evidence with respect to the question posed. A rigorous systematic review provided a current and comprehensive evidentiary base, which provided the context and direction for the development of recommendations.

CONCLUSIONS

Carcinoma of the glottis is usually diagnosed in the early phase, and both modalities of treatment have shown high cure rates. However, controversies in the treatment of early glottic cancer remain because of the lack of high-quality prospective analyses comparing endoscopic surgery versus radiotherapy. There is no evidence in favour of one treatment modality when considering likelihood of local control or overall survival. There is a suggestion that radiotherapy may be associated with less measureable perturbation of voice as compared to surgery but no significant differences were seen in patient perception. The likelihood of laryngeal preservation may be higher when surgery can be offered as initial treatment. Future research should focus on conducting RCTs or prospective comparative studies, with ample follow-up time, that focus on functional outcomes of patients with early glottic cancer.

Evidence-Based Series 5-2: Section 3

The Role of Endolaryngeal Surgery (With or Without Laser) versus Radiotherapy in the Management of Early (T1) Glottic Cancer: EBS Development Methods and External Review Process

J. Yoo, C. Lacchetti, A. Hammond, R. Gilbert, and the Head and Neck Cancer Disease Site Group

A Quality Initiative of the Program in Evidence-Based Care (PEBC), Cancer Care Ontario (CCO)

Report Date: March 14, 2012

THE PROGRAM IN EVIDENCE-BASED CARE

The Program in Evidence-based Care (PEBC) is an initiative of the Ontario provincial cancer system, Cancer Care Ontario (CCO) (1). The PEBC mandate is to improve the lives of Ontarians affected by cancer, through the development, dissemination, implementation, and evaluation of evidence-based products designed to facilitate clinical, planning, and policy decisions about cancer care.

The PEBC supports a network of disease-specific panels, termed Disease Site Groups (DSGs), as well as other groups or panels called together for a specific topic, all mandated to develop the PEBC products. These panels are comprised of clinicians, other health care providers and decision makers, methodologists, and community representatives from across the province.

The PEBC is well known for producing evidence-based guidelines, known as Evidence-based Series (EBS) reports, using the methods of the Practice Guidelines Development Cycle (1,2). The EBS report consists of an evidentiary base (typically a systematic review), an interpretation of and consensus agreement on that evidence by our Groups or Panels, the resulting recommendations, and an external review by Ontario clinicians and other stakeholders in the province for whom the topic is relevant. The PEBC has a formal standardized process to ensure the currency of each document, through the periodic review and evaluation of the scientific literature and, where appropriate, the integration of that literature with the original guideline information.

The Evidence-Based Series

Each EBS is comprised of three sections:

- **Section 1: Guideline Recommendations.** Contains the clinical recommendations derived from a systematic review of the clinical and scientific literature and its
interpretation by the Group or Panel involved and a formalized external review in Ontario by review participants.

- **Section 2: Evidentiary Base.** Presents the comprehensive evidentiary/systematic review of the clinical and scientific research on the topic and the conclusions reached by the Group or Panel.

- **Section 3: EBS Development Methods and External Review Process.** Summarizes the EBS development process and the results of the formal external review of the draft version of **Section 1: Guideline Recommendations** and **Section 2: Evidentiary Base**.

**DEVELOPMENT OF THIS EVIDENCE-BASED SERIES**

**Development and Internal Review**

This EBS was developed by the Head and Neck Cancer DSG of the CCO PEBC. The series is a convenient and up-to-date source of the best available evidence on the role of endolaryngeal surgery (with or without laser) versus radiotherapy in the management of early (T1) glottic cancer, developed through review of the evidentiary base, evidence synthesis, and input from external review participants in Ontario.

**Report Approval Panel Review and Approval**

Prior to the submission of this EBS draft report for External Review, the report was reviewed and approved by the PEBC Report Approval Panel, a panel that includes oncologists and whose members have clinical and methodological expertise. Key issues raised by the Report Approval Panel and the modifications made by the Head and Neck DSG (indicated by ➢) are listed below:

1. Although it is clear for the main users of this guideline, other non-content-expert users may have difficulty with the fact that laryngeal cancer and glottic cancer are used interchangeably.
   ➢ The first paragraph now outlines the glottis as the region of the larynx that contains the true vocal cords, and glottic remains the term used through the document.

2. It is unclear from the guideline or the website who the authors and collaborators are.
   ➢ Appendix 1 now outlines all members of the Head & Neck DSG, their affiliations, and disciplines.

3. It should be stressed in the Recommendations that no well designed, prospective, randomized trials have been published to help provide strong, unequivocal recommendations and that the following recommendations are based largely on retrospective, lower quality data.
   ➢ The following has been added to the qualifying statement: There is currently no well designed, prospective, randomized controlled trial (RCT) that compares endolaryngeal surgery and radiation therapy. Thus, these recommendations are largely based on other comparative study designs.

4. Some of the recommendations/statements are a bit too strong for the quality/quantity of the data and may require some rewording.
   ➢ In the last paragraph of the Discussion, “provided an ABUNDANT evidentiary base” was replaced with “a current and comprehensive evidentiary base” and the last sentence of Conclusions, “WAS ASSOCIATED” was changed to “MAY BE associated”.

5. The first sentence of the Qualifying Statement: “RT requires long-term cooperation and tolerance and it is a once only application technique”, is too indistinct and should be revised.
This sentence has been modified to now read, “Radiotherapy requires patient cooperation for daily treatment for four to six weeks and re-irradiation is not an option in cases of recurrence.”

6. Some emphasis is put on the improvement in cause-specific mortality observed at 15 years in the Thurner et al paper. There are concerns about this being a real phenomenon when no hint of an improvement was seen at 5 or 10 years.

The statistically significant result seen at 15 years was something the authors attributed to additional and earlier relapses in the RT patients compared to the surgical group. This statement has now been added.

7. Although no conflicts are declared, it should be explored as to whether the various techniques used can lead to income differentials large enough to potentially cause the appearance of conflict.

Financial interests from professional income are indeed considered in the PEBC’s Conflict of Interest Form. No conflicts were declared.

8. The guideline question describes 3 outcomes: locoregional control, laryngeal preservation rates and voice outcomes. The actual outcomes reported in table 2 are OS, DFS and CSS. Suggest changing first outcome in guideline question to “oncologic outcomes” or spelling out OS, DFS and CSS to better align the question with the synthesized data.

Survival has now been added as an outcome of interest.

External Review by Ontario Clinicians and Other Experts

The PEBC external review process is two-pronged and includes a targeted peer review that is intended to obtain direct feedback on the draft report from a small number of specified content experts and a professional consultation that is intended to facilitate dissemination of the final guidance report to Ontario practitioners.

Following the review and discussion of Section 1: Recommendations and Section 2: Evidentiary Base of this EBS and the review and approval of the report by the PEBC Report Approval Panel, the Head and Neck Cancer DSG circulated Sections 1 and 2 to external review participants for review and feedback. Box 1 summarizes the draft recommendations and supporting evidence developed by the DSG.
therapy. The choice between treatment modalities should be based on patient and clinician preferences and general medical condition.

QUALIFYING STATEMENT
There is currently no well-designed, prospective, randomized controlled trial (RCT) that compares endolaryngeal surgery and radiation therapy. Thus, these recommendations are based primarily on other comparative study designs. Although not substantiated by the evidence, several factors are important considerations when deciding between surgery and radiotherapy for early glottic cancer. Location of disease is one factor. Anterior commissure involvement may be a factor that favours a recommendation of radiotherapy over surgery due to a common opinion that voice outcomes are particularly affected. Tumours localized to the midportion of the vocal fold, and where endoscopic accessibility is uncompromised, may be considered ideal candidates for surgery. Other important practical considerations include the ability for patients to tolerate a general anaesthetic, which is required for surgery. In contrast, radiotherapy requires patient cooperation for daily treatment for four to six weeks. Partial laryngeal surgery, including revision endoscopic surgery, is possible for local recurrence following surgery. However, re-irradiation is not an option in cases of recurrence.

KEY EVIDENCE
There is a lack of high-quality evidence to explicitly inform the guideline question. Notwithstanding, the recommendation is based on the best available evidence and a consensus of expert clinical opinion of the Head and Neck Cancer Disease Site Group.

One meta-analysis, fifteen cohort studies and two cross-sectional studies comparing endolaryngeal surgery (with or without laser) to radiation therapy in patients with early glottic cancer comprised the evidence base.

- No statistically significant differences in overall survival or disease-free survival were detected. One retrospective cohort study (1) did report a significant (p=0.003) 15-year cause-specific survival benefit in surgically treated patients (100%) over those treated with radiation therapy (91%). This result was not consistent with four other retrospective cohort studies (2,3-5) that also considered cause-specific mortality and showed no significant differences. The meta-analysis [6] detected no statistically significant laryngectomy-free survival benefits associated with laser surgery when compared to radiation therapy (odds ratio [OR], 0.73; 95% confidence interval [CI], 0.39-1.35).

- One meta-analysis (6) found no statistically significant difference in local control between radiation therapy and laser surgery (OR, 0.66; 95% CI, 0.41 to 1.05). One (7) of eight retrospective cohort studies reported a marginally significant better control rate in surgically treated patients (89%) over those treated with radiotherapy (75%) when only T1a patients were considered (p=0.05). One retrospective cohort study [1] also reported a significant difference in recurrence rates favouring surgery. Thurnher et al (1) found a recurrence rate of 30.5% in those undergoing radiation therapy versus 9.9% in the patients treated with laser excision (p=0.001). The remaining five studies did not report any such significant differences in recurrence rates between treatment groups.

- Laryngeal preservation rates were found to be better with surgery, (with or without laser) as compared to radiation in five studies (1,5,7-9), while one
study found a marginally significant better preservation rate with radiation therapy (p=0.051) (10).  
- Post-treatment voice and speech quality was assessed by clinician perceptual analysis in one retrospective cohort study (11), which found that the difference between radiation therapy patients and those treated surgically did not reach statistical significance. In five studies that analyzed patient self-perception, three (12-14) found no statistically significant difference between treatment groups, one (15) found radiation therapy patients scored significantly better, and one (16) study reported surgically treated patients scored better. One meta-analysis (6) found conflicting results. It detected significantly better maximum phonation time and fundamental frequency in the radiation therapy patients but reported that the perturbation measures of jitter and shimmer significantly favoured the patients undergoing transoral laser surgery.

**Methods**

**Targeted Peer Review:** During the guideline development process, six targeted peer reviewers from Ontario and Alberta, considered to be clinical and/or methodological experts on the topic, were identified by the working group. Several weeks prior to completion of the draft report, the nominees were contacted by email and asked to serve as reviewers. Three reviewers agreed and the draft report and a questionnaire were sent via email for their review. The questionnaire consisted of items evaluating the methods, results, and interpretive summary used to inform the draft recommendations and whether the draft recommendations should be approved as a guideline. Written comments were invited. The questionnaire and draft document were sent out on August 25, 2011. Follow-up reminders were sent at two weeks (email) and at four weeks (telephone call). The Head and Neck DSG reviewed the results of the survey.

**Professional Consultation:** Feedback was obtained through a brief online survey of health care professionals who are the intended users of the guideline. All Head and Neck professionals from Ontario in the PEBC database were contacted by email to inform them of the survey. Participants were asked to rate the overall quality of the guideline (Section 1) and whether they would use and/or recommend it. Written comments were invited. Participants were contacted by email and directed to the survey website where they were provided with access to the survey, the guideline recommendations (Section 1) and the evidentiary base (Section 2). The notification email was sent on January 23, 2012. The consultation period ended on March 5, 2012. The Head and Neck DSG reviewed the results of the survey.

**Results**

**Targeted Peer Review:** Three responses were received from six reviewers. Key results of the feedback survey are summarized in Table 1.

**Table 1. Responses to nine items on the targeted peer reviewer questionnaire.**

| | Strongly Disagree (1) | Neutral (3) | Strongly Agree (5) |
---|---|---|---|
7. I would make use of this guideline in my professional decisions. | | | 2 |
8. I would recommend this guideline for use in practice. | 1 | 2 |

9. What are the barriers or enablers to the implementation of this guideline report?
   Limitations of the evidence, institutional treatment bias, possible technical limitations or lack of experience/training in transoral microsurgery at some centres, and access to CO2 laser and microlaryngeal equipment were recorded as potential barriers. Another reviewer thought there would be no such barriers to implementation.
   One reviewer suggested that most clinicians already accept the equivalence of the two treatment modalities in this patient population and have the facilities to deliver either modality, thereby enabling the implementation of this guideline.

Summary of Written Comments
The written comments received from the reviewers were predominantly favourable and included positive feedback on the appropriateness of methods used, transparency of the process, organization of the guideline, suitability of the included stakeholders, and quality of the systematic review. Reviewers acknowledged the limitations of the poor quality data and commented on the lack of evidence to support any one treatment modality over the other. Based on the available information, one reviewer suggested both treatment options should be discussed with patients in a multidisciplinary fashion. Finally, a suggestion of conducting a cost-utility analysis was raised. However, with cost analyses outside of the scope of the PEBC guidelines, no modifications were taken based on this feedback.

Professional Consultation: Fifteen responses were received. Key results of the feedback survey are summarized in Table 2.

Table 2. Responses to four items on the professional consultation survey.

| General Questions: Overall Guideline Assessment | Lowest Quality (1) | (2) | (3) | (4) | Highest Quality (5) |
---|---|---|---|---|---|
1. Rate the overall quality of the guideline report. | 1 (6.7) | 0 | 4 (26.7) | 7 (46.7) | 3 (20) |
4. What are the barriers or enablers to the implementation of this guideline report?
   Practitioners listed barriers to the implementation of this guideline, which included the following:

1. **Limitation of the evidence**
   Several practitioners commented that the lack of high quality evidence may act as a barrier to uptake.

2. **Existing biases**
   Many practitioners reported that existing biases based on the discipline of the treating physician could act as a barrier to the implementation of this guideline. Additionally, incorrect patient preconception was suggested as a potential barrier. Some remarked that this guideline will do nothing but reinforces the prejudices already in play amongst the advocates of each treatment modality.

3. **Economic**
   Economic consideration should be given regarding the two treatment modalities to enable the guideline implementation.

4. **Patient suitability**
   Practitioners remarked that not all patients are candidates for laryngeal laser surgery and this may hinder implementation. Criticism over patient selection in the surgery group in the included literature was also commented upon and suggested as a further potential hurdle.

**Summary of Written Comments**

Three of the fifteen responders to professional consultation provided additional written comments. These included positive feedback on the summary, the need for a large prospective study comparing radiation without salvage surgery to laser surgery, and a comment on the advantage of partial surgery in that it enables future use of XRT in second malignancies.

**Modifications/Actions**

The majority of the comments received from responding Ontario practitioner are already recognized by the DSG and many are addressed within the evidence-based report. However, with the limitation of the included evidence commented on by many external reviewers, a statement renewing the systematic process taken and the emphasis placed on higher quality evidence when available was added to the discussion. No further modifications to the guideline were taken.
Conclusion
This EBS report reflects the integration of feedback obtained through the external review process with final approval given by the Head and Neck DSG and the Report Approval Panel of the PEBC. Updates of the report will be conducted as new evidence informing the question of interest emerges.
